²Department of Geosciences, University of Arizona, 1040 E. 4th Street, Tucson, Arizona USA

³Sandia National Laboratories, Albuquerque, New Mexico, USA

Key Points:

- The CESM2.2 release includes several enhancements to the spectral-element dynamical core, including two new Arctic refined mesh configurations.
- Uniform resolution grids degrade the surface mass balance of the Greenland Ice Sheet compared with equivalent low resolution latitude-longitude grids.
- The refined Arctic meshes substantially improve the surface mass balance over all low resolution grids.

15 **Abstract**

16 Six different configurations, a mixture of grids and atmospheric dynamical cores
 17 available in the Community Earth System Model, version 2.2 (CESM2.2), are evaluated
 18 for their skill in representing the climate of the Arctic and the surface mass balance of
 19 the Greenland Ice Sheet (GrIS). The conventional 1° – 2° uniform resolution grids sys-
 20 tematically overestimate both accumulation and ablation over the GrIS. Of these con-
 21 ventional grids, the latitude-longitude grids outperform the quasi-uniform unstructured
 22 grids owing to their higher degrees of freedom in representing the GrIS. Two Arctic-refined
 23 meshes, with $1/4^{\circ}$ and $1/8^{\circ}$ refinement over Greenland, are documented as newly sup-
 24 ported configurations in CESM2.2. The Arctic meshes substantially improve the sim-
 25 ultated clouds and precipitation rates in the Arctic. Over Greenland, these meshes skill-
 26 fully represent accumulation and ablation processes, leading to a more realistic GrIS sur-
 27 face mass balance. As CESM is in the process of transitioning away from conventional
 28 latitude-longitude grids, these new Arctic refined meshes improve the representation of
 29 polar processes in CESM by recovering resolution lost in the transition to quasi-uniform
 30 grids.

31 **1 Introduction**

32 General Circulation Models (GCMs) are powerful tools for understanding the me-
 33 teorology and climate of the high latitudes, which are among the most sensitive regions
 34 on Earth to global and environmental change. GCMs differ vastly in their numerical treat-
 35 ment of polar regions because of the so-called *pole-problem* (Williamson, 2007). The pole
 36 problem refers to numerical instability arising from the convergence of meridian lines into
 37 polar singularities on latitude-longitude grids (e.g., Figure 1a, hereafter referred to as
 38 *lat-lon* grids). Depending on the numerics, methods exist to suppress this instability, and
 39 lat-lon grids may be advantageous for polar processes by representing structures with
 40 finer resolution than elsewhere in the computational domain. With the recent trend to-
 41 wards globally uniform unstructured grids, any potential benefits of lat-lon grids in po-
 42 lar regions may be lost. In this study, we evaluate a number of grids and dynamical cores
 43 (hereafter referred to as *dycores*) available in the Community Earth System Model, ver-
 44 sion 2.2 (CESM2.2; Danabasoglu et al., 2020), including new variable-resolution grids,
 45 to understand their impacts on the simulated Arctic climate. We focus specifically on
 46 the climate and surface mass balance of the Greenland Ice Sheet.

47 In the 1970s, the pole problem was largely defeated through the adoption of effi-
 48 cient spectral transform methods in GCMs (see Williamson, 2007, and references therein).
 49 These methods transform grid point fields into a global, isotropic representation in wave
 50 space, where linear operators (e.g., horizontal derivatives) in the (truncated) equation
 51 set can be solved exactly. While spectral transform methods are still used today, local
 52 numerical methods have become desirable for their ability to run efficiently on massively
 53 parallel systems. The pole problem has thus re-emerged in contemporary climate mod-
 54 els that use lat-lon grids, and some combination of reduced grids (modified lat-lon grids,
 55 with cells elongated in the longitudinal direction over the polar regions) and polar fil-
 56 ters are necessary to ameliorate this numerical instability (Jablonowski & Williamson,
 57 2011). Polar filters subdue the growth of unstable computational modes by applying ad-
 58 ditional damping to the numerical solution over polar regions. This damping reduces the
 59 effective resolution in polar regions such that the resolved scales are *approximately* the
 60 same everywhere on the grid. We emphasize *approximately*, since it is at least conceiv-
 61 able that marginal increases in effective resolution occur over polar region in lat-lon grids,
 62 despite polar filtering, since resolved waves can be represented with more grid points than
 63 at lower latitudes.

64 Dycores built on lat-lon grids have some advantages over unstructured grids. Lat-
 65 lon coordinate lines are orthogonal, and aligned with zonally symmetric circulations that

characterize many large-scale features of Earth's atmosphere. Lauritzen et al. (2010) has experimented with rotating lat-lon models such that their coordinate lines no longer align with an idealized, zonally balanced circulation. For the finite-volume lat-lon dycore considered in this paper (hereafter *FV*), numerical errors were shown to be largest when the polar singularity is rotated into the baroclinic zone (45°N latitude), generating spurious wave growth much earlier in the simulation than for other rotation angles. This illustrates the advantages of coordinate surfaces aligned with latitude bands, albeit an extreme example where the polar singularity and the polar filter are also contributing to the spurious wave growth. The unstructured grids all generate spurious baroclinic waves earlier on in the simulations than the (unrotated) lat-lon models, although the unstructured model considered in this paper, the spectral-element dycore (hereafter *SE*), holds a balanced zonal flow without spurious wave growth appreciably longer than the rotated FV experiments (Lauritzen et al., 2010). And unlike *FV*, the *SE* dycore has the same error characteristics regardless of how the grid is rotated.

The polar filter in the *FV* model impedes efficiency at large processor (CPU) counts because it requires a spectral transform, which have large communication overhead (Suarez & Takacs, 1995; Dennis et al., 2012). Unstructured grids support quasi-uniform grid spacing globally, and there is no pole-problem (e.g., Figure 1c). Conversely, unstructured grids are becoming increasingly common due to their improved performance on massively parallel systems and lack of constraints on grid structure (Taylor et al., 1997; Putman & Lin, 2007; Wan et al., 2013). This grid flexibility allows for the adoption of variable-resolution grids (e.g., Figure 2; hereafter abbreviated as *VR*), sometimes referred to as regional grid refinement. In principle, grid refinement over polar regions can make up for any loss of resolution in transitioning away from lat-lon grids (e.g., Figure 2). However, local grid refinement comes at the cost of a smaller CFL-limited time step in the refined region; the CFL-condition — short for Courant–Friedrichs–Lewy condition — is a necessary condition for numerical stability when using discrete data in time and space.

It is important to emphasize that the pole-problem is a distinctive feature of the dycore in atmospheric models. Polar filters do not directly interfere with the physical parameterizations, nor do they have any bearing on the surface models; e.g., the land model can take full advantage of the greater number of grid cells in polar regions on lat-lon grids. This is particularly relevant for the surface mass balance of the Greenland Ice Sheet (*SMB*; the integrated sum of precipitation and runoff), which relies on hydrological processes represented in the land model.

The *SMB* of the Greenland Ice Sheet (hereafter *GrIS*) is determined by processes occurring over a range of scales that are difficult to represent in GCMs (Pollard, 2010). *GrIS* precipitation is concentrated at the ice-sheet margins, where steep topographic slopes drive orographic precipitation. The truncated topography used by low resolution GCMs enables moisture to penetrate well into the *GrIS* interior, manifesting as a positive precipitation bias (Pollard & Groups, 2000; van Kampenhout et al., 2018). *GrIS* ablation areas (marginal regions where seasonal melting exceeds the annual mass input from precipitation) are typically less than 100 km wide and are confined to low-lying areas or regions with low precipitation. These narrow ablation zones are not fully resolved in low resolution GCMs, and may further degrade the simulated *SMB*. For example, CESM, version 2.0 (CESM2) underestimates ablation in the northern *GrIS*, leading to unrealistic ice advance when run with an interactive ice sheet component (Lofverstrom et al., 2020).

Regional climate models (RCMs) are commonly relied upon to provide more accurate *SMB* estimates. The limited area domain used by RCMs permits the use of high resolution grids, capable of resolving *SMB* processes, that can skillfully simulate the *GrIS* *SMB* (Box et al., 2004; Rae et al., 2012; Van Angelen et al., 2012; Fettweis et al., 2013; Mottram et al., 2017; Noël et al., 2018). However, unlike GCMs, RCMs are not a freely evolving system and the atmospheric state must be prescribed at the lateral boundaries

119 of the model domain. The inability of the RCM solution to influence larger-scale dynamics
 120 outside the RCM domain (due to the prescribed boundary conditions) severely limits this approach from properly representing the role of the GrIS in the climate system.
 121 In addition, the boundary conditions are derived from a separate host model, which introduces
 122 inconsistencies due to differences in model design between the host model and the RCM.
 123

125 In order to retain the benefits of RCMs in a GCM, van Kampenhout et al. (2018)
 126 utilized the VR capabilities of the SE dycore in CESM, generating a grid where Greenland
 127 is represented with $1/4^\circ$ resolution, and elsewhere with the more conventional 1°
 128 resolution. The simulated SMB compared favorably to the SMB from RCMs and obser-
 129 vations. The VR approach is therefore emerging as a powerful tool for simulating and
 130 understanding the GrIS and its response to different forcing scenarios, in the freely evolv-
 131 ing GCM framework.

132 The SE dycore has been included in the model since CESM, version 1, but has been
 133 under active development ever since. This includes the switch to a dry-mass vertical co-
 134 ordinate (Lauritzen et al., 2018) and incorporation of an accelerated multi-tracer trans-
 135 port scheme (Lauritzen et al., 2017), made available in CESM2. This paper documents
 136 several additional enhancements to the SE dycore as part of the release of CESM2.2. These
 137 include three new VR configurations (Figure 2), two Arctic meshes and a Contiguous
 138 United-States mesh (**CONUS**; featured in Pfister et al. (2020)). While there are dozens of
 139 published studies using VR in CESM (e.g., Zarzycki et al., 2014; Rhoades et al., 2016;
 140 Gettelman et al., 2017; Burakowski et al., 2019; Bambach et al., 2021), these studies ei-
 141 ther used development code or collaborated closely with model developers. CESM2.2 is
 142 the first code release that contains out of the box VR functionality in CESM.

143 This study compares the representation of Arctic regions using the SE and FV dy-
 144 cores in CESM2.2 (see description below), as these two dycores treat high latitudes (i.e.,
 145 the pole problem) in different ways. Section 2 documents the grids, dycores, and phys-
 146 ical parameterizations used in this study, and also describes the experiments, datasets,
 147 and evaluation methods. Section 3 analyzes the results of the experiments, and Section 4
 148 provides a general discussion and conclusions.

149 2 Methods

150 2.1 Dynamical cores

151 The atmospheric component of CESM2.2 (Danabasoglu et al., 2020), the Commu-
 152 nity Atmosphere Model, version 6.3 (CAM6; Gettelman et al., 2019; Craig et al., 2021),
 153 supports several different atmospheric dynamical cores. These include dycores on lat-
 154 ion grids, such as finite-volume (FV; Lin, 2004) and Eulerian spectral transform (EUL;
 155 Collins et al., 2006) models, and dycores built on unstructured grids, including spectral-
 156 element (SE; Lauritzen et al., 2018) and finite-volume 3 (FV3; Putman & Lin, 2007) mod-
 157 els. This study compares the performance of the SE and FV dycores, omitting the EUL
 158 and FV3 dycores. CESM2 runs submitted to the Coupled Model Intercomparison Project
 159 Phase 6 (Eyring et al., 2016) used the FV dycore, whereas the SE dycore is often used
 160 for global high-resolution simulations (e.g., Small et al., 2014; Bacmeister & Coauthors,
 161 2018; Chang et al., 2020) due to its higher throughput on massively parallel systems (Dennis
 162 et al., 2012).

163 2.1.1 Finite-volume (FV) dynamical core

164 The FV dycore is a hydrostatic model that integrates the equations of motion us-
 165 ing a finite-volume discretization on a spherical lat-lon grid (Lin & Rood, 1997). The
 166 2D dynamics evolve in floating Lagrangian layers that are periodically mapped to an Eu-

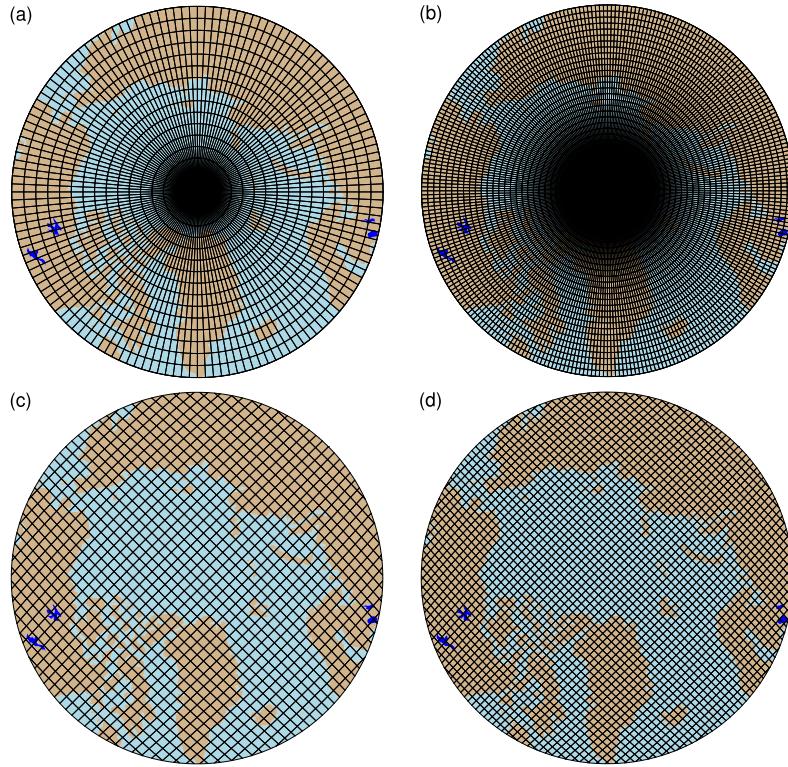

Figure 1. Computational grids for the uniform $1^\circ - 2^\circ$ grids in this study. Grids names after Table 1, (a) f19, (b) f09, (c) ne30pg2 and (d) ne30pg3.

lerian reference grid in the vertical (Lin, 2004). Hyperviscous damping is applied to the divergent modes, and is increased in the top few layers (referred to as a *sponge layer*) to prevent undesirable interactions with the model top, such as wave reflection (Lauritzen et al., 2011). A polar filter damps computational instability due to the convergence of meridians, permitting a longer time step. It takes the form of a Fourier filter in the zonal direction, with the damping coefficients increasing monotonically in the meridional direction (Suarez & Takacs, 1995). The form of the filter is designed to slow down the propagation of large zonal wave-numbers to satisfy the CFL condition of the shortest resolved wave at some reference latitude.

2.1.2 Spectral-element (SE) dynamical core

The SE dycore is a hydrostatic model that integrates the equations of motion using a high-order continuous Galerkin method (Taylor et al., 1997; Taylor & Fournier, 2010). The computational domain is a cubed-sphere grid tiled with quadrilateral elements (see Figure 2). Each element contains a fourth-order basis set in each horizontal direction, with the solution defined at the roots of the basis functions, the Gauss-Lobatto-Legendre quadrature points. This results in 16 nodal points per element, with 12 of the points lying on the (shared) element boundary. Communication between elements uses the direct stiffness summation (Canuto et al., 2007), which applies a numerical flux to the element boundaries to reconcile overlapping nodal values and produce a continuous global basis set.

As with the FV dycore, the dynamics evolve in floating Lagrangian layers that are subsequently mapped to an Eulerian reference grid. A dry mass vertical coordinate was

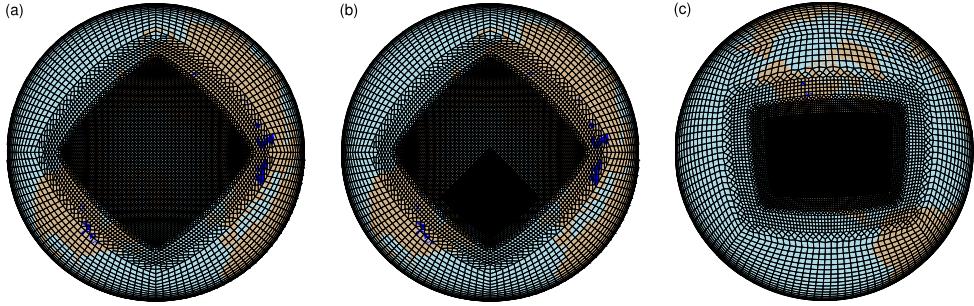

Figure 2. Variable-resolution grids available in CESM2.2, (a) `Arctic`, (b) `Arctic - GrIS` and (c) `CONUS`. Note what is shown is the element grid; the computational grid has 3×3 independent grid points per element.

recently implemented for thermodynamic consistency with condensates (Lauritzen et al., 2018). The 2D dynamics have no implicit dissipation, and so hyperviscosity operators are applied to all prognostic variables to remove spurious numerical errors (Dennis et al., 2012). Laplacian damping is applied in the sponge layer.

The SE dycore supports regional grid refinement via its VR configuration, requiring two enhancements over uniform-resolution setups. Firstly, as the numerical viscosity increases with resolution, explicit hyperviscosity relaxes according to the local element size, reducing in strength by an order of magnitude per halving of the grid spacing. A tensor-hyperviscosity formulation is used (Guba et al., 2014), which adjusts the coefficients in two orthogonal directions to more accurately target highly distorted quadrilateral elements. Secondly, the topography boundary conditions are smoothed in a way that does not excite grid scale modes, and so the NCAR topography software (Lauritzen et al., 2015) has been modified to scale the smoothing radius by the local element size, resulting in rougher topography in the refinement zone.

For SE grids with quasi-uniform grid spacing, the SE tracer transport scheme is replaced with the Conservative Semi-Lagrangian Multi-tracer transport scheme (CSLAM) (Lauritzen et al., 2017). Atmospheric tracers have large, nearly discontinuous horizontal gradients that are difficult to represent with spectral methods, which are prone to oscillatory “Gibbs-ringing” errors (Rasch & Williamson, 1990). CSLAM has improved tracer property preservation and accelerated multi-tracer transport. It uses a separate grid from the spectral-element dynamics, dividing each element into 3×3 control volumes with quasi-equal area. The physical parameterizations are computed from the state on the CSLAM grid, which has clear advantages over the original SE dycore in which the physics are evaluated Gauss-Lobatto-Legendre points (Herrington et al., 2018).

2.2 Grids

We evaluate model simulations on six different grids in this study (Table 1). The FV dycore is run with nominal 1° and 2° grid spacing, referred to as `f09` and `f19`, respectively (Figure 1a,b). We also run the 1° equivalent of the SE-CSLAM grid, referred to as `ne30pg3` (Figure 1d), where ne refers to a grid with $ne \times ne$ elements per cubed-sphere face, and pg denotes that there are $pg \times pg$ control volumes per element for computing the physics. We run an additional 1° SE-CSLAM simulation with the physical parameterizations computed on a grid with 2×2 control volumes per element, `ne30pg2` (Figure 1c; Herrington et al., 2019, note CSLAM is still run on the 3×3 control volume grid).

grid name	dycore	Δx_{eq} (km)	Δx_{refine} (km)	Δt_{phys} (s)
f19	FV	278	-	1800
f09	FV	139	-	1800
ne30pg2	SE-CSLAM	167	-	1800
ne30pg3	SE-CSLAM	111	-	1800
ne30pg3*	SE-CSLAM	111	-	450
Arctic	SE	111	28	450
Arctic – GrIS	SE	111	14	225

Table 1. Grids and dycores used in this study. Δx_{eq} is the average equatorial grid spacing, Δx_{refine} is the grid spacing in the refined region (if applicable), and Δt_{phys} is the physics time step. FV refers to the finite-volume dycore, SE the spectral-element dycore, and SE-CSLAM the spectral-element dycore with CSLAM tracer advection. We use the ne30pg3 grid for two runs with different values of Δt_{phys} .

Three VR meshes were developed for the CESM2.2 release to support grid refinement over the Arctic and the United States (Figure 2). This paper serves as the official documentation of these grids. The VR meshes were developed using the software package SQuadgen (<https://github.com/ClimateGlobalChange/squadgen>). The **Arctic** grid is a 1° grid with $1/4^{\circ}$ regional refinement over the broader Arctic region. The **Arctic–GrIS** grid is identical to the **Arctic** grid, but with an additional patch covering the island of Greenland with $1/8^{\circ}$ resolution. The **CONUS** grid contains $1/8^{\circ}$ refinement over the United States, and 1° everywhere else. The **CONUS** grid is not discussed any further in this paper; see Pfister et al. (2020) for simulations with the **CONUS** grid.

The accuracy of the simulated surface mass balance is expected to be sensitive to grid resolution. Figure 3b shows the average grid spacing over the Greenland Ice Sheet (*GrIS* hereafter) in all six grids in this study. The **ne30pg2** grid has the coarsest representation with an average grid spacing (Δx) of $\Delta x = 160$ km, and the **Arctic–GrIS** grid has the highest resolution with an average grid spacing of $\Delta x = 14.6$ km, similar to the 11 km grid spacing of the RACMO2.3 grid. The **ne30pg3** grid has an average $\Delta x = 111.2$ km, substantially coarser than the **f09** grid, with an average $\Delta x = 60$ km. Although **ne30pg3** and **f09** have similar average grid spacing over the entire globe, and comparable computational costs, the convergence of meridians on the FV grid enhances the resolution over the *GrIS*. The **Arctic** grid has an average grid spacing of $\Delta x = 27.8$ km, and is about 10 times more expensive than the 1° models. The **Arctic–GrIS** grid is about twice as expensive as the **Arctic** grid.

The physics time step depends on the grid resolution. Increased horizontal resolution permits faster vertical velocities that reduce characteristic time scales, so the physics time step is reduced to avoid large time truncation errors (Herrington & Reed, 2018). The **Arctic** and **Arctic–GrIS** grids are run with a $4\times$ and $8\times$ reduction in physics time step relative to the default 1800 s time step used in the 1° and 2° grids (Table 1).

All grids and dycores in this study use 32 hybrid pressure-sigma levels in the vertical, with a model top of 2 hPa or about 40 km. However, note that any grid or dycore can in principle be run with a higher model top or finer vertical resolution.

2.3 Physical parameterizations

All simulations in this study use the CAM6 physical parameterization package (hereafter referred to as the *physics*; Gettelman et al., 2019). The physics in CAM6 differs from its predecessors through the incorporation of high-order turbulence closure, Cloud Layers Unified by Binormals (CLUBB; Golaz et al., 2002; Bogenschutz et al., 2013), which jointly acts as a planetary boundary layer, shallow convection, and cloud macrophysics

scheme. CLUBB is coupled with the MG2 microphysics scheme (Gettelman & Morrison, 2015; Gettelman et al., 2015), which computes prognostic precipitation and uses classical nucleation theory to represent cloud ice for improved cloud-aerosol interactions. Deep convection is parameterized using a convective quasi-equilibrium, mass flux scheme (Zhang & McFarlane, 1995; Neale et al., 2008) and includes convective momentum transport (Richter et al., 2010). Boundary layer form drag is modeled after Beljaars et al. (2004), and orographic gravity wave drag is represented with an anisotropic method informed by the orientation of topographic ridges at the sub-grid scale (the ridge orientation is derived from a high-resolution, global topography dataset (J. J. Danielson & Gesch, 2011)).

Initial simulations with the `ne30pg3` SE grid produced weaker shortwave cloud forcing relative to the tuned finite-volume dycore in the standard CESM2 configuration. The SE dycore in CESM2.2 therefore has two CLUBB parameter changes to provide more realistic cloud forcing and top-of-atmosphere radiation balance. We reduced the width of the sub-grid distribution of vertical velocity (`clubb_gamma` = 0.308 → 0.270) and also reduced the strength of the damping for horizontal component of turbulent energy (`clubb_c14` = 2.2 → 1.6) to increase cloudiness. For a description of how CLUBB parameters impact the simulated climate, see Guo et al. (2015).

2.4 Simulated surface mass balance (SMB)

All grids and dycores simulate the GrIS SMB, which is the sum of mass accumulation of precipitation and mass loss from ablation. The latter is the sum of evaporation, sublimation and liquid runoff, with runoff being a combination of liquid precipitation and snow and ice melt. Not all liquid precipitation or snow/ice melt runs off the ice sheet; this water can penetrate pore spaces in the snowpack/firn layer and freeze, increasing the ice mass. These relevant SMB processes are represented by different CESM components, but it is the Community Land Model, version 5 (CLM; Lawrence et al., 2019), that aggregates these processes and computes the SMB.

CLM runs on the same grid as the atmosphere, and uses a downscaling technique to account for sub-grid variability in SMB. In short, the ice sheet patch in a CLM grid cell is subdivided into 10 elevation classes (ECs), each with a distinct surface energy balance and SMB. The area fraction of each EC is derived from a high-resolution GrIS elevation dataset. The near-surface air temperature, humidity, and air density are calculated for each EC using an assumed lapse rate and the elevation difference from the grid-cell mean. Precipitation from CAM is repartitioned into solid or liquid based on the surface temperature of the EC; precipitation falls as snow for temperatures between $T < -2^{\circ}$ C, as rain for $T > 0^{\circ}$ C, and as a linear combination of rain and snow for temperatures between -2° C and 0° C. Snow accumulation in each EC is limited to a depth of 10 m liquid water equivalent. Any snow above the 10 m cap contributes towards ice accumulation in the SMB. Refreezing of liquid water within the snowpack is an additional source of ice. Integrating over all ECs, weighting by the area fractions, provides a more accurate SMB than would be found using the grid-cell mean elevation. For a more detailed description of how the SMB is computed in CESM, we refer the reader to Lipscomb et al. (2013); Sellevold et al. (2019); van Kampenhout et al. (2020); Muntjewerf et al. (2021).

Changes in ice depth, but not snow depth, count toward the SMB. That is, snow accumulation above the 10 m cap contributes a positive SMB, and surface ice melting (after melting of the overlying snow) yields a negative SMB. Since snow in the accumulation zone must reach the cap to simulate a positive SMB, the snow depths on the VR grids were spun up by forcing CLM in standalone mode, cycling over data from a 20-year Arctic FHISt simulation (a model simulation with prescribed, observed sea-surface conditions) for about 500 years. The uniform-resolution grids are initialized with the SMB

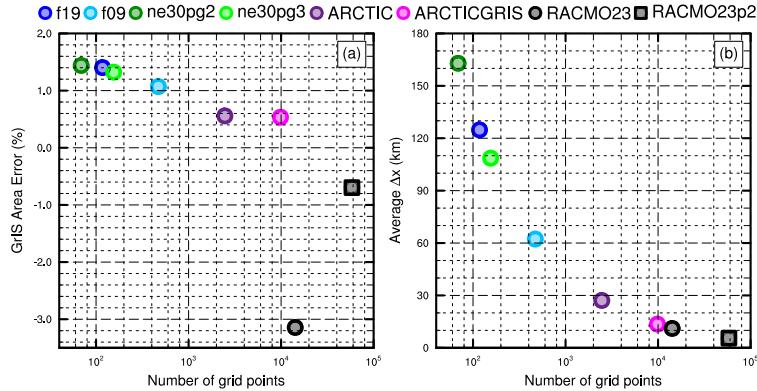

Figure 3. The spatial properties of the GrIS as represented by different grids in this study. (Left) GrIS area error, computed as the relative differences from a 4-km dataset used to create the CESM ice masks, (right) approximate average grid spacing over GrIS.

from an existing **f09** spun-up initial condition. In the simulations described here, the GrIS is prescribed at its observed, modern extent and thickness.

2.5 SMB Analysis

We seek to integrate SMB components over a GrIS ice mask and to diagnose their contributions to the GrIS mass budget. However, the ice masks vary across the grids, especially in comparison to the RACMO3.2 ice mask, whose total area is about 3% less than that of the reference dataset (Figure 3). CLM’s dataset creation tool generates the model ice mask by mapping a high-resolution dataset to the target grid using the Earth System Modeling Framework (ESMF) first-order conservative remapping algorithm (Team et al., 2021). The figure suggests that the mapping errors are less than 1.5% across the CESM2 grids. The area errors in Figure 3 may seem small, but even 1 – 2% area differences can lead to large differences in integrated SMB (Hansen et al., 2022).

We have taken a common-ice-mask approach by mapping all model fields to the lowest-resolution grids, i.e., the **f19** and **ne30pg2** grids, and integrating over these low-resolution ice masks. The use of low-resolution common ice masks is a conservative decision, and is justified because we seek to use first-order remapping algorithms to map fields to the common ice mask, which is not generally reliable when mapping to a higher-resolution grid than the source grid. We use two remapping algorithms: ESMF first-order conservative and the TempestRemap (Ullrich & Taylor, 2015) high-order monotone algorithm. Since mapping errors are sensitive to grid type, we evaluate all quantities on both common ice masks, the **f19** and **ne30pg2** masks. Thus, we evaluate an integrated quantity on a given grid up to four times to estimate the uncertainty due to differences in grid type and remapping algorithms.

The SMB is expressed in a form that is agnostic of water phase, a total water mass balance, to facilitate comparisons across different grids with different ice masks and to increase consistency with the variables available in the RACMO datasets. The SMB for total water can be expressed as:

$$SMB = \text{accumulation} + \text{runoff} + \text{evaporation}/\text{sublimation}, \quad (1)$$

where all terms have consistent sign conventions (positive values contribute mass, and negative values reduce mass). The accumulation source term refers to the combined solid and liquid precipitation, runoff refers to the liquid water sink, and evaporation/sublimation

338 is the vapor sink. Since the runoff term aggregates many processes, we isolate the melting
 339 contribution by also tracking the combined melt of snow and ice. Note that this SMB
 340 expression is different from the internally computed SMB described in the previous sec-
 341 tion.

342 We consider two approaches for mapping and integrating the SMB components over
 343 the common ice masks:

- 344 1. Map the grid-cell mean quantities to the common grid, and integrate the mapped
 345 fields over the common ice masks.
- 346 2. Map the patch-level quantities (i.e., the state over the ice fractional component
 347 of the grid cell) to the common grid, and integrate the mapped fields over the com-
 348 mon ice masks.

349 Note that we are mapping to low-resolution grids that have larger GrIS areas than
 350 the source grids (Figure 3). Since the components of equation 1 are not confined to the
 351 ice mask, method 1 reconstructs the SMB over the portion of the common ice mask that
 352 is outside the ice mask on the source grid. While this may be a an acceptable way to re-
 353 construct the mass source terms over different ice masks, ice melt is zero outside the source
 354 ice mask, and so method 1 will underestimate the mass sink term. This underestima-
 355 tion is systematic in method 2, where all variables are exclusive to the ice mask; map-
 356 ping to a lower-resolution grid will dilute a field of non-zero values over the ice mask with
 357 a field of zeros outside the ice mask. However, patch-level values for processes exclusive
 358 to the ice mask (e.g., ice melt) will on average have larger magnitudes than the the grid-
 359 mean quantities used in method 1.

360 The different error characteristics of the two methods are used to diversify the en-
 361 semble. Each of the four regridding combinations (with conservative and high-order remap-
 362 ping to the f09 and ne30pg2 grids) are repeated with each method, resulting in (up to)
 363 eight values for each integrated quantity. Unfortunately, the patch-level values of evap-
 364 oration/sublimation are not available from the model output, and we estimate their con-
 365 tribution by zeroing out the field for grid cells that have no ice, prior to mapping to the
 366 common ice mask. This will degrade the SMB estimates using method 2, however we
 367 are more interested in characterizing the behavior of individual processes across grids
 368 and dycores, expressed as the components of the SMB, rather than the SMB itself.

369 2.6 Experimental design

370 All simulations described here use an identical transient 1979-1998 Atmospheric
 371 Model Inter-comparison Project (AMIP) configuration, with prescribed monthly sea-surface
 372 temperature and sea ice following Hurrell et al. (2008). In CESM terminology, AMIP
 373 simulations use the FHIST computational set and run out of the box in CESM2.2.

374 2.7 Observational Datasets

375 We use several observational datasets (Table 2) to assess the performance of the
 376 simulations. SMB datasets are gathered from multiple sources. Regional Atmospheric
 377 Climate Model, version 2.3 11km (RACMO23; Noël et al., 2015) and version 2.3p2 5.5km
 378 (RACMO2.3p2; Noël et al., 2018, 2019) are RCM simulations targeting Greenland, forced
 379 by ERA renalyses products at the domain's lateral boundaries. The RACMO simula-
 380 tions have been shown to perform skillfully against observations and are often used as
 381 modeling targets (e.g., Evans et al., 2019; van Kampenhout et al., 2020).

382 In-situ SMB (snow pit and ice cores) and radar accumulation datasets (e.g., Ice-
 383 Bridge) are maintained in The Land Ice Verification and Validation toolkit (LIVVkit),
 384 version 2.1 (Evans et al., 2019). However, these point-wise measurements are difficult

data product	years used in this study	resolution	citation
ERA5	1979-1998	1/4°	Copernicus (2019)
CERES-EBAF ED4.1	2003-2020	1°	Loeb et al. (2018)
CALIPSO-GOCCP	2006-2017	1°	Chepfer et al. (2010)
RACMO2.3	1979-1998	11 km	Noël et al. (2015)
RACMO2.3p2	1979-1998	5.5 km	Noël et al. (2019)

Table 2. Description of observational datasets used in this study.

385 to compare to model output spanning several different grids, especially since the SMB
 386 from each elevation class is not available from the model output. We used a nearest-neighbor
 387 technique for an initial analysis, which showed that the model biases are similar to those
 388 computed using the RACMO datasets. Because of the uncertainty of comparing grid-
 389 ded fields to point-wise measurements, and the lack of information added with regard
 390 to model biases, we omitted these datasets from our analysis.

391 3 Results

392 3.1 Tropospheric temperatures

393 Before delving into the simulated Arctic climate conditions, we assess the global
 394 mean differences between the various grids and dycores. Figure 4 shows 1979-1998 an-
 395 nual mean, zonal mean height plots expressed as differences between uniform-resolution
 396 grids and dycores. The **f09** grid is warmer than the **f19** grid, primarily in the mid-to-
 397 high latitudes throughout the depth of the troposphere. This is a common response to
 398 increasing horizontal resolution in GCMs (Pope & Stratton, 2002; Roeckner et al., 2006).
 399 Herrington and Reed (2020) have shown that this occurs in CAM due to higher resolved
 400 vertical velocities which, in turn, generate more condensational heating in the CLUBB
 401 macrophyiscs. The right panel in Figure 4a supports this interpretation, showing an in-
 402 crease in the climatological CLUBB heating at all latitudes in the **f09** grid, but with the
 403 largest increase in the mid-latitudes.

404 As the SE dycore is less diffusive than the FV dycore, the resolved vertical veloc-
 405 ities are larger in the SE dycore, and so the **ne30pg3** troposphere is modestly warmer
 406 than **f09** (Figure 4b). The stratosphere responds differently, with **ne30pg3** much cooler
 407 than **f09** in the mid-to-high latitudes. Figure 4c also shows small temperature differences
 408 between **ne30pg3** and **ne30pg2**, with **ne30pg3** slightly warmer near the tropopause at
 409 high latitudes. This is consistent with the similar climates found for these two grids by
 410 Herrington et al. (2019).

411 Comparing the VR grids to the uniform-resolution grids is complicated because we
 412 simultaneously increase the resolution and reduce the physics time-step, both of which
 413 influence the solution (Williamson, 2008). We therefore run an additional **ne30pg3** sim-
 414 ulation with the shorter physics time step used in the **Arctic** grid (450 s), referred to
 415 as **ne30pg3*** (Table 1). Figure 5a shows the difference between **ne30pg3*** and **ne30pg3**
 416 for climatological summer temperatures in zonal-mean height space. The troposphere
 417 is warmer with the reduced time step, and the mechanism is similar in that the shorter
 418 time step increases resolved vertical velocities (not shown) and CLUBB heating (right
 419 panel in Figure 5a). Figure 5b shows the difference in climatological summer temper-
 420 ature between the **Arctic** grid and the **ne30pg3*** grid. With the same physics time step,
 421 the greater condensational heating and warmer temperatures are confined to the refined
 422 Arctic region.

423 Figure 5c shows that the **Arctic-GrIS** grid is much warmer than the **Arctic** grid
 424 in the Arctic summer. This may be due, in part, to the shorter physics time step, but

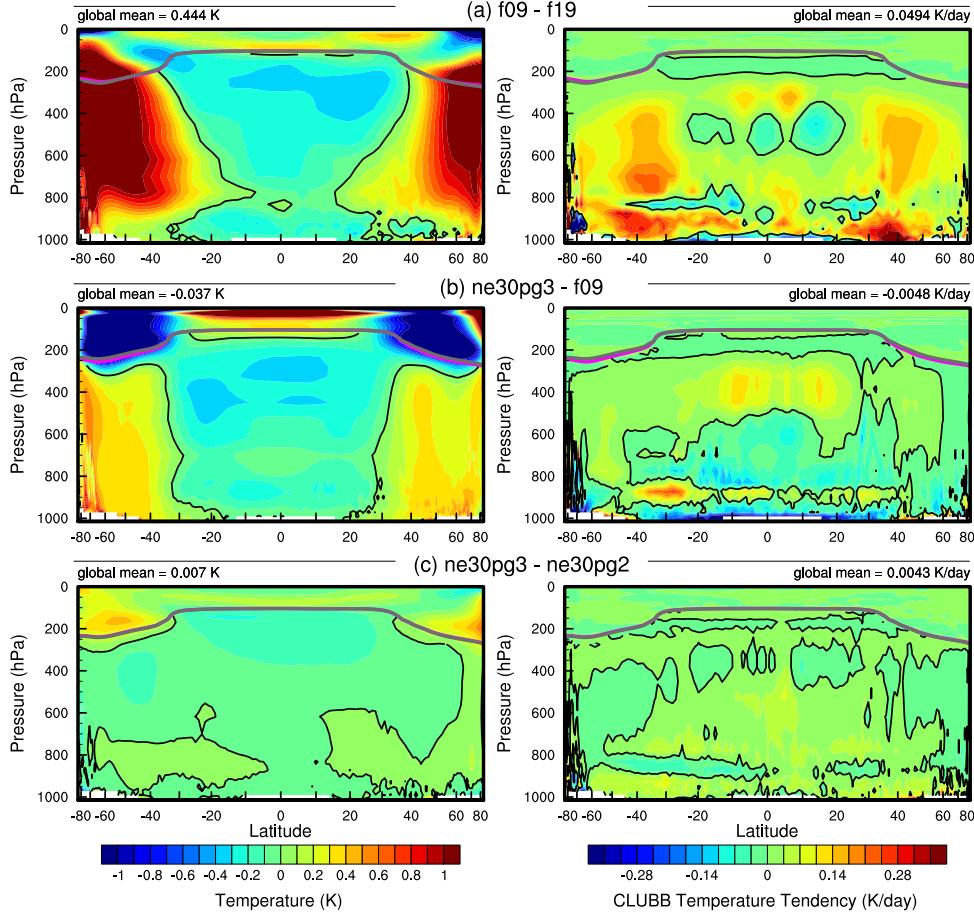

Figure 4. 1979–1998 annual mean temperature (left column) and CLUBB temperature tendencies (right column) in zonal mean height space, expressed as differences between the various 1° – 2° grids. The thick grey and magenta lines are the tropopause for the control run and the test run, respectively.

the temperature response is too large to be explained by enhanced condensational heating from CLUBB alone. This summer warming appears to be a result of variations in the stationary wave pattern, with a swath of anomalous southerly winds to the west of Greenland (not shown). This dynamic response is interesting, because other than the physics time step, the only difference between the Arctic – GrIS and Arctic runs is the doubling of resolution over Greenland. This behavior will be explored further in a future study.

It is useful to understand summer temperature biases due to their control on ice and snow melt over the GrIS (Ohmura, 2001). Figure 6 shows the 1979–1998 lower troposphere summer temperature bias relative to ERA5, computed by equating a layer mean virtual temperature with the 500–1000 hPa geopotential thickness. The results are consistent with the zonal mean height plots; increasing resolution from f19 to f09 warms the climate, and the 1° SE grids are warmer than the FV grids. The FV summer temperatures are persistently colder than ERA5, whereas the 1° SE grids are not as cold, and are actually warmer than ERA5 at high-latitudes, north of 75° . All grids show a north-south gradient in bias over Greenland, with the summer temperature bias more positive

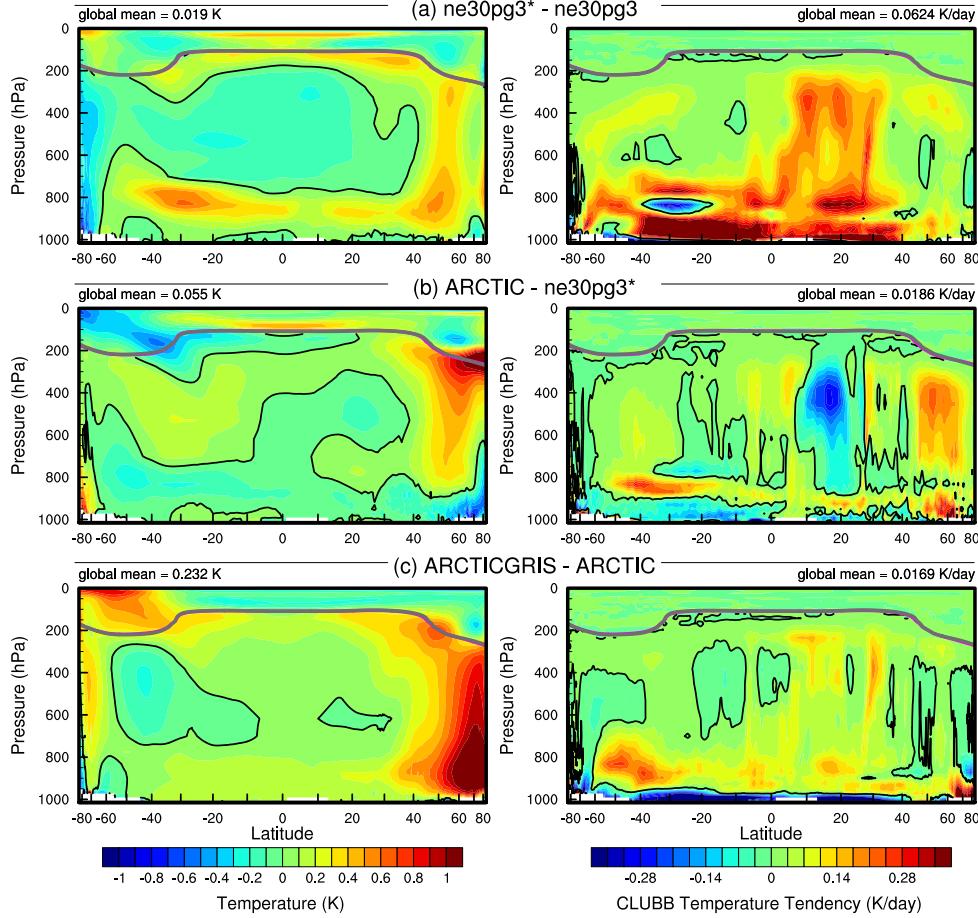

Figure 5. As in Figure 4 but for the short-time-step experiment and the VR grids. The fields plotted are for the climatological northern hemisphere summer. We focus on summer because that is when the resolution response is largest, and the refined regions are located in the northern hemisphere.

for the northern part of the ice sheet. This pattern is also evident in the near surface temperature bias over Greenland (not shown).

The **Arctic** grid has summer temperatures similar to the 1° SE grids, but is slightly warmer over northern Eurasia and the North Pole (Figure 6). An anomalous cooling patch forms to the west of Greenland, centered over Baffin Island. The **Arctic – GrIS** grid is warmer than the **Arctic** grid over most of the Arctic, but with a similar spatial pattern of summer temperature bias.

Some of these temperature differences may be related to differences in summer cloudiness. Figure 7 shows the summer shortwave cloud forcing bias in the six runs, using the CERES product. Shortwave cloud forcing quantifies the impact of clouds on shortwave radiation, taken as the difference between all-sky and clear-sky shortwave radiative fluxes at the top of the atmosphere. A negative bias corresponds to excessive reflection and cooling. The uniform grids have similar biases, with the clouds reflecting 20–40 W/m² too much shortwave radiation over a wide swath of the Arctic, primarily the land masses. There is also a halo of positive bias (clouds not reflective enough) around the ocean perimeter of Greenland. The **Arctic** grid has much smaller cloud forcing biases over the Arc-

tic land masses, but is still too reflective over Alaska, the Canadian Archipelago, and parts of Eurasia. Compared to the **Arctic** grid, the **Arctic – GrIS** grid vastly reduces the cloud forcing bias over Eurasia, and also improves the bias over North America. In both VR grids, the halo of positive shortwave cloud forcing bias around the perimeter of Greenland is absent.

The summer cloud forcing biases are consistent with the summer temperature biases in Figure 6 – regions where clouds are too reflective coincide with regions that are too cold. While we have not quantified the contribution of cloud biases to the cooler Arctic temperatures, shortwave radiation is a crucial component of the Arctic energy budget during summer. The shortwave cloud forcing biases are on the order of 10 W/m², which is a significant fraction of the total absorbed shortwave during Arctic summer (Serreze et al., 2007) and is therefore likely a factor contributing to the cooler temperatures.

3.2 Clouds and precipitation over Greenland

In addition to summer temperatures, shortwave radiation is an important determinant of snow and ice melt. Figure 8 shows the summer incident shortwave radiation bias at the surface over Greenland and surrounding seas. The top panel shows the bias relative to the RACMO2.3p2 dataset, and the middle panel relative to the CERES dataset. The halo of excessive incident shortwave radiation around the coasts of Greenland is apparent for both datasets in relation to the coarser grids, consistent with the shortwave cloud forcing biases in Figure 7.

The ice sheet interior receives too little shortwave radiation in the coarser grids. On the VR grids, both the interior shortwave deficit and the excessive shortwave around the ocean perimeter are improved. This suggests that the coarse grid clouds are too thick in the interior of Greenland and too thin around the perimeter, which is consistent with the total summer cloud fraction bias, computed from the CALIPSO cloud dataset and shown in the bottom panel of Figure 8. Note that total cloud fraction characterizes the cloud field at all vertical levels, and attenuates the changes arising from any single layer due to the occurrence of overlapping clouds at other levels. The VR grids exhibit an overall improvement in total cloud fraction bias, relative to the coarse grids.

The top panel of Figure 9 show the annual climatological mean precipitation bias over the GrIS, expressed as the fractional difference from the RACMO2.3p2 solution. The coarse 1° – 2° grids have large, positive biases centered over the southern dome. The **Arctic** grid reduces this bias substantially, and the **Arctic–GrIS** grid reduces it further, with precipitation centers migrating from the interior toward the margins.

The more accurate representation of orographic precipitation in the VR grids is consistent with the cloud and radiation biases, cf. Figures 7, 8, and 9. The agreement of the cloud, radiation and precipitation biases in and around Greenland from multiple independent datasets indicates that the biases are a robust feature of the coarser grids. The reduced biases in the VR grids suggest that the deficiencies of the coarse grids are due to insufficient horizontal resolution, consistent with previous findings that coarse GCMs have large, positive precipitation biases over Greenland (Pollard & Groups, 2000; van Kampenhout et al., 2018).

3.3 Greenland surface mass balance

Table 3 shows the 1979-1998 climatological SMB components for each grid, compared with RACMO. The values in the table are averages over the ensemble of mapping methods to the common ice masks described in section 2.5, and the RACMO values are averages over both RACMO datasets (Table 2). Table 3 also contains (in parenthesis) the SMB components derived from evaluating the integrals on each model's native grid and ice mask. Of note is the large reduction in melt rates compared to the values com-

grid name	accumulation	total melt	runoff	sublimation	SMB
RACMO	681.7 (733.5)	-318.6 (-436.4)	-189.1 (-258.5)	-34.5 (-38.8)	458.1 (436.2)
ne30pg2	1007. (973.4)	-519.9 (-647.3)	-381.9 (-347.0)	-33.9 (-32.1)	591.2 (594.3)
ne30pg3	931.0 (909.3)	-540.8 (-686.7)	-375.8 (-330.1)	-34.1 (-32.6)	521.2 (546.6)
f19	884.9 (913.5)	-414.0 (-546.5)	-284.0 (-284.3)	-36.5 (-37.5)	564.4 (591.7)
f09	873.9 (882.1)	-389.1 (-482.3)	-256.1 (-212.3)	-37.3 (-37.4)	580.5 (632.4)
Arctic	784.1 (818.6)	-335.5 (-436.8)	-215.8 (-194.2)	-42.4 (-43.9)	526.0 (580.5)
Arctic – GrIS	693.8 (747.3)	-437.3 (-610.4)	-276.8 (-307.8)	-48.1 (-51.8)	369.0 (387.7)

Table 3. 1979–1998 surface mass balance of the Greenland Ice Sheet in Gt/yr. Values shown are using the common ice mask approach described in the methods section, whereas values in parentheses are from integrating over the native grid and ice mask.

puted on the native grid, illustrating the dissipation of this quantity discussed in section 2.5. For integrated precipitation, the differences between the native and common-ice-mask approaches are much smaller, since the combined solid/liquid precipitation rates are not directly tied to the ice mask.

One of the most interesting aspects of the SMB calculations is that the coarse grids are characterized by too much precipitation and too much melting and runoff, compared with RACMO. The SMB in the coarse grids therefore have smaller errors than the individual components (Table 3), because large errors in the source and sink terms offset one another when added together. Such compensating errors highlights the importance of understanding the extent to which a model is getting the SMB right for the right reasons.

Figure 10 shows time series of annually integrated precipitation and snow/ice melt over the GrIS for the various different grids and dycores, and RACMO in black. The 1979–1998 climatological mean values from Table 3 are shown as circles on the right side of the panels. The uniform $1^\circ - 2^\circ$ grids have positive precipitation biases, whereas the VR grids have the smallest biases, with precipitation comparable to RACMO. The f19 and f09 grids perform similarly, with +110 Gt/yr bias, whereas ne30pg3 is biased by about +165 Gt/yr and ne30pg2 by +230 Gt/yr. The larger biases on the uniform-resolution SE grids relative to the FV grids are consistent with the coarser GrIS resolution on the SE grids (Figure 3).

The combined annual snow/ice melt shown in the bottom panel of Figure 10 indicates that the Arctic grid simulates the most realistic melt rates, with the other grids having more melt than RACMO. The Arctic–GrIS grid over-predicts melting by about 125 Gt/yr. This is likely due to an anomalously warm lower troposphere during the summer, relative to the Arctic run (Figure 6). The f19 and f09 melting rates are improved over Arctic–GrIS, overestimating melt by only 70–90 Gt/yr. The SE grids have the largest positive melt bias, between 200–220 Gt/yr.

To illustrate the regional behavior of the SMB components, Figure 11 shows the precipitation and combined snow/ice melt integrated over the basins defined by Rignot and Mouginot (2012). The uncertainty due to differences in basin area is larger than for GrIS-wide integrals, owing to the differences in basin boundaries as represented by the common ice masks, which are shown in the f19 and ne30pg2 panels of Figure 9. Nonetheless, the regional totals in Figure 11 correctly show the southeast and southwest basins have the most accumulation. In all basins, accumulation decreases monotonically with increasing grid resolution, though with some exceptions. The Arctic–GrIS grid simulates less precipitation than RACMO in the central-east and southeast basins, and is closest of all grids to RACMO in the large southwest basin.

543 The basin-integrated melt rates in Figure 11 depend on the dycore. The uniform-
 544 resolution SE grids have the largest positive biases in all basins. The **Arctic–GrIS** grid
 545 is a close second, while the FV grids have systematically smaller melt-rates. The “second-
 546 place” standing of **Arctic–GrIS** is somewhat unexpected, as this grid has the warmest
 547 lower-troposphere summer temperatures (Figure 6) and greatest incident shortwave ra-
 548 diation (Figure 8), yet it has less melting than the uniform-resolution SE grids.

549 Lower troposphere temperature is not a strict proxy for melting; e.g., it may not
 550 capture microclimate effects as a result of a better representation of the low-elevation
 551 ablation zones. Positive degree-days (PDD; Braithwaite, 1984), which accumulate the
 552 near-surface temperature in $^{\circ}\text{C}$ for days with temperature above freezing, are a more ac-
 553 curate proxy. PDD is nonlinear in mean monthly temperature (Reeh, 1991). We com-
 554 pute it from monthly mean 2-meter temperature using the method of Calov and Greve
 555 (2005), assuming a fixed monthly mean standard deviation of 3°C and a degree-day fac-
 556 tor of $5 \text{ mm d}^{-1} ^{\circ}\text{C}^{-1}$.

557 Figure 11c shows the basin-integrated PDD melt estimate. In the large southeast
 558 and southwest basins (and all the other western basins), the **ne30pg3** grid has larger PDD-
 559 based melt than the **Arctic–GrIS** grid. The FV grids also have large PDD-based melt
 560 in the southwest basin, relative to **Arctic–GrIS**. The PDD plots indicate that the near-
 561 surface temperatures (which contribute to melt) are not well approximated by the sum-
 562 mer lower-troposphere temperatures in Figure 6.

563 The bottom panel of Figure 9 presents the biases in the combined ice/snow melt
 564 as map plots. These plots show that the largest melt biases are on the southeast and north-
 565 west coasts, where large coarse-grid cells overlap with the ocean. One possibility is that
 566 these problematic grid cells are situated at lower elevations than the true ice sheet sur-
 567 face, leading to a warm bias and too much melt. Figure 12 shows the representation of
 568 the ice sheet surface along two transects on the different grids, compared to the high-
 569 resolution dataset used to generate CAM topographic boundary conditions (J. Daniel-
 570 son & Gesch, 2011; Lauritzen et al., 2015). The two transects are shown in Figure 9: the
 571 east-west “K-transsect” in southwest Greenland and a transect extending from the cen-
 572 tral dome down to the Kangerlussuaq glacier on the southeast coast. The 1° – 2° grids
 573 are noticeably coarse, with only a handful of grid cells populating the transect. The **f09**
 574 grid is a bit of an exception, since the grid cells become narrow in the meridional direc-
 575 tion at high latitudes, and a larger number of grid cells populate an east-west transect.
 576 The VR grids are more skillful at reproducing the steep margins of the ice sheet, cap-
 577 turing the parabolic shape of the GrIS margins.

578 The transects in Figure 12 show that the ice sheet surface on the coarse grids is
 579 not systematically lower than the true surface in ablation zones. Rather, the smooth-
 580 ing and flattening of the raw topography, necessary to prevent the model from exciting
 581 grid-scale numerical modes, causes the lower-elevation ablation zones to extend beyond
 582 the true ice sheet margin, where they lie above the actual ice surface. The **f19** grid has
 583 both the smoothest topography and the flattest ice sheet since its dynamics are coars-
 584 est (**f09**, **ne30pg2** and **ne30pg3** use identical smoothing). This suggests that coarser mod-
 585 els will tend to elevate the ablation zones and thereby depress melt rates.

586 Figure 12 also shows the ice margin boundary, illustrating that the ablation zone
 587 lies in a narrow horizontal band where the ice sheet rapidly plunges to sea-level. Due to
 588 this abrupt transition, coarse grids will commonly represent the ablation zone with grid
 589 cells containing mixtures of ice-covered and ice-free regions. We hypothesize that coarser
 590 models have larger melt biases because summer melting is confined to these mixed ice/land/ocean
 591 grid cells. CLM deals with land heterogeneity in a complex and sophisticated manner,
 592 but CAM only sees the homogenized state after volume averaging over the sub-grid mix-
 593 ture. Thus, warm ice-free land patches in a grid cell may unduly influence the climate
 594 over the entire grid cell, causing a warm bias over the ice-covered patch.

595 Figure 13 shows mean melt bias, relative to both RACMO datasets, conditionally
 596 sampled based on grid cell ice fraction in the GrIS region. Errors are computed using
 597 the common ice mask approach described in section 2.5, and so the grid cell ice fraction
 598 are taken from the common masks. The figure shows that coarser grids generally have
 599 two peaks in ice fraction space; a bump in positive melting errors in the 0-20% range,
 600 and another in the fully ice-covered cells. Also shown are the ± 1 standard deviation of
 601 the biases for each bin. They indicate that the biases in 0-20% bins are mostly contained
 602 in the positive bias region (a fractional bias greater than 0), whereas the fully-covered
 603 ice cells have a wider distribution, with many grid cells also containing negative melt-
 604 ing biases. The excessive melting in the 0-20% ice fraction bins supports our hypothe-
 605 sis that the prevalence of mixed-grid cells in the ablation zone on coarse grids is respon-
 606 sible for their large melt bias.

607 (Any idea why the errors are smaller in the cells with intermediate ice fraction? I
 608 wouldn't have expected this.) Rene - is the melt map consistent with the bin figure? Small-
 609 est errors are interior points which correspond to glacier fraction bin of 1, which the largest
 610 errors. ARH - I can check. The bin figure is fractional change so its a different metric,
 611 which could explain the apparent inconsistency.

612 3.4 Precipitation extremes

613 Synoptic storms are tracked using TempestExtremes atmospheric feature detec-
 614 tion software (Ullrich et al., 2021). As the **Arctic** grid contains $1/4^\circ$ refinement north
 615 of about 45° latitude, the storm tracker is applied to this region for the **Arctic** and **ne30pg3**
 616 runs to identify differences in storm characteristics due to horizontal resolution. The com-
 617 posite mean precipitation maps are similar between the two grids, and exhibit the iconic
 618 comma structure of synoptic cyclones (not shown). Marcus - no need to mention if not
 619 shown.

620 Figure 14 shows monthly PDFs of the precipitation rates associated with storms.
 621 The PDFs are constructed by sampling all the precipitation rates within 30° of the storm
 622 center, for each point on the storm track and for all storms. The PDFs are evaluated on
 623 an identical composite grid for all runs, and so storm statistics are not impacted by dif-
 624 ferences in output resolution. The **Arctic** run has larger extreme precipitation rates com-
 625 pared to **ne30pg3** in every month, but the increase is greatest in the summer months,
 626 which coincides with the most extreme events of the year. This is primarily due to in-
 627 creased resolution and not the reduced physics times-step; the **ne30pg3*** run only marginally
 628 increases the extreme precipitation rates compared with **ne30pg3** (Figure 14).

629 The extreme precipitation rates in the **Arctic** run are closer than **ne30pg3** to the
 630 ERA5 reanalysis (Figure 14). It is difficult to know how much the extreme precipitation
 631 rates in ERA5 are constrained by data assimilation, or whether these precipitation rates
 632 are due to using a similar $1/4^\circ$ model as the **Arctic** grid. However, it is well documented
 633 that $1/4^\circ$ models are more skillful at simulating extreme events (Bacmeister et al., 2013;
 634 Obrien et al., 2016). A more realistic representation of extreme precipitation events is
 635 an additional benefit of the VR grids.

636 4 Conclusions

637 Running CESM2.2 in an AMIP-style configuration, we have evaluated six grids from
 638 two dynamical cores for their performance over the Arctic and in simulating the GrIS
 639 SMB. The $1 - 2^\circ$ finite-volume grids have enhanced resolution over polar regions due
 640 to the convergence of meridian lines, although a polar filter is used to prevent spurious
 641 atmospheric features from forming at this higher resolution. Spectral-element grids com-
 642 parable to the resolution of the finite-volume grids have an isotropic grid structure where
 643 the grid resolution is similar over the entire model domain. We developed two VR grids

644 and introduced them into CESM2.2 as part of this work. Both use the spectral-element
 645 dycore; the **Arctic** grid has $1/4^\circ$ refinement over the broader Arctic, whereas the **Arctic–GrIS**
 646 grid is identical except for a $1/8^\circ$ patch of refinement over Greenland. A third VR
 647 grid, CONUS, is also available in CESM2.2.

648 In general, the FV grids have colder summer temperatures over the Arctic com-
 649 pared with the SE grids (including the VR grids). The cloud biases in all the uniform-
 650 resolution grids, whether FV or SE, are similar, in general being too cloudy over Arc-
 651 tic land masses. **Marcus - hard to parse this sentence.** The VR grids reduce the cloud bi-
 652 ases. It should be emphasized that our analysis is specific to the Arctic summer because
 653 of its relevance to GrIS melt rates; an improved representation of clouds in the Arctic
 654 does not imply improved clouds at lower latitudes.

655 At the regional level, there is a halo of negative cloud bias (/colorblueI got con-
 656 fused about signs here, because section 3 talks about a halo of positive cloud SW forc-
 657 ing bias, which corresponds to a negative bias in cloud amounts. Maybe replace 'cloud
 658 bias' with 'cloudiness bias' or something similar?) around the ocean perimeter of Green-
 659 land on all $1-2^\circ$ grids, but not the VR grids. This halo bias coincides with a positive
 660 cloud bias over the ice sheet interior. This anomaly pattern has been attributed to de-
 661 ficient orographic precipitation on the coarser model grids. With overly smooth topog-
 662 raphy on the $1-2^\circ$ grids, synoptic systems moving into Greenland are not sufficiently
 663 lifted when encountering the steep ice margins. As a result, excess precipitation falls in
 664 the GrIS interior, instead of being concentrated on the steep coastal margins as shown
 665 by observations. This results in a positive precipitation and cloud bias in the ice sheet
 666 interior, and a halo of low cloud bias about the perimeter. The agreement of different
 667 observational data products on this bias lends confidence in the attribution of causes.
 668 The VR grids compare better to the observations and show that orographic precipita-
 669 tion in Greenland is largely resolved when the horizontal resolution is increased sufficiently.

670 We integrated the primary source and sink terms of the SMB equation over the GrIS
 671 for each of the six grids. The uniform $1-2^\circ$ grids have large positive accumulation bi-
 672 ases because they fail to resolve orographic precipitation. The uniform SE grids have larger
 673 accumulation biases, suggesting that the FV grids are more skillful for precipitation due
 674 to finer resolution over Greenland, despite a polar filter. The VR grids have the most
 675 accurate accumulation rates of all the grids.

676 The primary mass sink term of the GrIS, ice/snow melt, has similar biases. The
 677 uniform resolution SE grids have too much melt, while the FV grids have smaller biases.
 678 It is difficult to attribute these biases to grid resolution alone. The FV grids have colder
 679 summers, consistent with their lower melt bias. However, the **Arctic – GrIS** grid has
 680 the warmest summer temperatures of all grids, yet it has less melting than the uniform-
 681 resolution SE grids. This suggests that grid resolution is responsible for a large fraction
 682 of the melt biases. We propose a mechanism: Coarse grids represent ablation zones us-
 683 ing grid cells with mixed surface types, ice-covered and ice-free. The warmer ice-free patches
 684 may largely determine the mean state, leading to a warm bias over the ice-covered patches
 685 of the grid cell. This mechanism is supported by analysis of melt biases binned by grid-
 686 cell ice fraction.

687 The **Arctic** grid substantially improves the simulated Arctic climate, including pre-
 688 cipitation extremes and the Greenland SMB, compared to the uniform $1^\circ - 2^\circ$ grids.
 689 The **Arctic–GrIS** grid has the most realistic cloud and precipitation fields, but its sum-
 690 mer temperatures are too warm. The 1° FV model gives a surprisingly realistic SMB,
 691 likely due to the relatively fine resolution of Greenland on lat-lon grids. **It is also the most**
 692 **heavily tuned model configuration. May be worth mentioning here as well.** In particu-
 693 lar, a greater number of grid cells in the ablation zone reduces the influence of mixed ice-
 694 covered/ice-free grid cells that represent ablation poorly on the other uniform-resolution
 695 grids.

As modeling systems move away from lat-lon grids towards quasi-uniform unstructured grids, it is worth taking stock of whether this will degrade the simulated polar climate. We have found that the 1° FV model has clear advantages over the 1° SE model in simulating the surface mass balance of the GrIS. This finding will not interrupt the ongoing transition towards unstructured grids in CESM, largely driven by gains in computational efficiency, but it has inspired us to develop alternative configurations that recover or improve on the fidelity of polar climate. We have shown here (and in a prior companion study (van Kampenhout et al., 2018)) that for CESM, Arctic-refined meshes can substantially improve the simulated mass balances of the GrIS, even compared to the 1° grid. This should reassure the CESM modeling community that the ongoing transition away from lat-lon grids will not adversely impact CESM's usefulness as a state-of-the-art tool for simulating and understanding polar processes. (WHL: This last sentence may be too sanguine. Yes, we can recover the fidelity of Arctic simulations using VR grids, but (so far) only at a considerable cost in cpu-hours. This points to the need for an intermediate resolution that is more affordable, and/or model development or tuning that reduces the biases on coarse grids.) Andrew - Maybe better to just state that higher resolution is better: 1deg better than 2deg FV, and ne30 is coarser than 1deg at Greenland latitudes so it's worse. But VR has higher resolution so SR-VR is better. It's all about resolution.

We are working to develop a configuration of the `Arctic` grid that is fully-coupled with the CESM ocean and sea ice components and the Community Ice Sheet Model (CISM), to provide multi-century projections of the state of the GrIS and its contribution to sea-level rise. We have also developed a visualization of the `Arctic-GrIS` run, now available on youtube¹. Figure 15 shows a snapshot of this visualization, illustrating mesoscale katabatic winds descending the southeastern slopes of GrIS. These new grids and configurations will provide new opportunities for CESM polar science and aims to contribute to an improved understanding of the polar environment. (WHL: I replaced the previous last sentence because it seemed too much like an advertisement. However, this new ending seems weak. I wonder if we should say something about future work motivated by this study, for instance investigating grids and parameterizations that provide some of the same benefits as these VR grids but at lower cost.)

Appendix A Details on spectra-element dynamical core improvements since the CESM2.0 release

Since the CESM2.0 release of the spectral-element dynamical core documented in Lauritzen et al. (2018) some important algorithmic improvements have been implemented and released with CESM2.2. These pertain mainly to the flow over orography that, for the spectral-element dynamical core, can lead to noise aligned with the element boundaries (Herrington et al., 2018).

A1 Reference profiles

Significant improvement in removing noise for flow over orography can be achieved by using reference profiles for temperature and pressure

$$T^{(ref)} = T_0 + T_1 \Pi^{(ref)}, \quad (A1)$$

$$p_s^{(ref)} = p_0 \exp\left(-\frac{\Phi_s}{R^{(d)} T_{ref}}\right), \quad (A2)$$

(Simmons & Jiabin, 1991) where g gravity, $T_1 = \Gamma_0 T_{ref} c_p^{(d)} / g \approx 192K$ with standard lapse rate $\Gamma_0 \equiv 6.5K/km$ and $T_0 \equiv T_{ref} - T_1 \approx 97K$; $T_{ref} = 288K$ ($c_p^{(d)}$ specific heat

¹ https://www.youtube.com/watch?v=YwHgqDu75s8&t=4s&ab_channel=NCARVisLab

739 of dry air at constant pressure; $R^{(d)}$ gas constant for dry air), and Φ_s surface geopotential.
 740 The reference Exner function is

$$\Pi^{(ref)} = \left(\frac{p^{(ref)}}{p_0} \right)^\kappa \quad (\text{A3})$$

741 where $\kappa = \frac{R^{(d)}}{c_p^{(d)}}$. The reference surface pressure $p_0 = 1000\text{hPa}$ and at each model level
 742 the reference pressure $p^{(ref)}$ is computed from $p_s^{(ref)}$ and the standard hybrid coefficients

$$p^{(ref)}(\eta) = A(\eta)p_0 + B(\eta)p_s^{(ref)}, \quad (\text{A4})$$

743 where A and B are the standard hybrid coefficients (using a dry-mass generalized ver-
 744 tical mass coordinate η). These reference profiles are subtracted from the prognostic tem-
 745 perature and pressure-level-thickness states before applying hyperviscosity:

CESM2.0 → CESM2.2

$$\nabla_\eta^4 T \rightarrow \nabla_\eta^4 \left(T - T^{(ref)} \right), \quad (\text{A5})$$

$$\nabla_\eta^4 \delta p^{(d)} \rightarrow \nabla_\eta^4 \left(\delta p^{(d)} - \delta p^{(ref)} \right). \quad (\text{A6})$$

746 This reduces spurious transport of temperature and mass up/down-slope due to the hy-
 747 perviscosity operator.

748 A2 Rewriting the pressure gradient force (PGF)

749 In the CESM2.0 the following (standard) form of the pressure gradient term was
 750 used:

$$\nabla_\eta \Phi + \frac{1}{\rho} \nabla_\eta p, \quad (\text{A7})$$

751 where Φ is geopotential and $\rho = \frac{R^{(d)}T_v}{p}$ is density (for details see Lauritzen et al., 2018).
 752 To alleviate noise for flow over orography, we switched to an Exner pressure formulation
 753 following Taylor et al. (2020), which uses that (A7) can be written in terms of the Exner
 754 pressure

$$\nabla_\eta \Phi + c_p^{(d)} \theta_v \nabla_\eta \Pi, \quad (\text{A8})$$

755 where the Exner pressure is

$$\Pi \equiv \left(\frac{p}{p_0} \right)^\kappa. \quad (\text{A9})$$

756 The derivation showing that (A7) and (A8) are equivalent is shown here:

$$\begin{aligned} c_p^{(d)} \theta_v \nabla_\eta \Pi &= c_p^{(d)} \theta_v \nabla_\eta \left(\frac{p}{p_0} \right)^\kappa, \\ &= c_p^{(d)} \theta_v \kappa \left(\frac{p}{p_0} \right)^{\kappa-1} \nabla_\eta \left(\frac{p}{p_0} \right), \\ &= c_p^{(d)} \theta_v \kappa \Pi \left(\frac{p_0}{p} \right) \nabla_\eta \left(\frac{p}{p_0} \right), \\ &= \frac{c_p^{(d)} \theta_v \kappa \Pi}{p} \nabla_\eta p, \\ &= \frac{R^{(d)} \theta_v \Pi}{p} \nabla_\eta p, \\ &= \frac{R^{(d)} T_v}{p} \nabla_\eta p, \\ &= \frac{1}{\rho} \nabla_\eta p. \end{aligned}$$

757 Using the reference states from (Simmons & Jiabin, 1991),

$$\bar{T} = T_0 + T_1 \Pi, \quad (\text{A10})$$

$$\bar{\theta} = T_0/\Pi + T_1, \quad (\text{A11})$$

758 we can define a geopotential as a function of Exner pressure

$$\bar{\Phi} = -c_p^{(d)} (T_0 \log \Pi + T_1 \Pi - T_1). \quad (\text{A12})$$

759 This "balanced" geopotential obeys

$$c_p^{(d)} \bar{\theta} \nabla \Pi + \nabla \bar{\Phi} = 0 \quad (\text{A13})$$

760 for any Exner pressure. Subtracting this "reference" profile from the PGF yields

$$\begin{aligned} \nabla_\eta \Phi + c_p^{(d)} \theta_v \nabla_\eta \Pi &= \nabla_\eta (\Phi - \bar{\Phi}) + c_p^{(d)} (\theta_v - \bar{\theta}) \nabla_\eta \Pi, \\ &= \nabla_\eta \Phi + c_p^{(d)} \theta_v \nabla_\eta \Pi + c_p^{(d)} T_0 \left[\nabla_\eta \log \Pi - \frac{1}{\Pi} \nabla_\eta \Pi \right]. \end{aligned} \quad (\text{A14})$$

761 In the continuum, the two formulations (left and right-hand side of (A14)) are identi-
762 cal. But under discretization, the second formulation can have much less truncation er-
763 ror.

764 A3 Results

765 [Adam: have you defined ne30np4 in the main text?]

766 One year averages of vertical pressure velocity at 500hPa (`OMEGA500`) have been
767 found to be a useful quantity to detect spurious up or down-drafts induced by steep orog-
768 raphy (Figure A1). While the true solution is not known, strong vertical velocities aligned
769 with element edges that are not found in the CAM-FV reference solution (Figure A1(a))
770 are likely not physical (spurious). The older CESM2.0 version of SE (Figure A1(d)) us-
771 ing the "traditional" discretization of the PGF, (A14), exhibits significant spurious noise
772 patters around steep orography compared to CAM-FV (e.g., around Himalayas and An-
773 des). This is strongly alleviated by switching to the Exner formulation of the PGF (A8;
774 Figure A1(c)). By also subtracting reference profiles from pressure-level thickness and
775 temperature, equations (A5) and (A6) respectively, reduces strong up-down drafts fur-
776 ther (Figure A1(d)). Switching to the CAM-SE-CSLAM version where physics ten-
777 dencies are computed on an quasi-equal area physics grid and using the CSLAM transport
778 scheme, marginal improvements are observed in terms of a smoother vertical velocity field
779 (Figure A1(e,f)). The configuration shown in Figure A1(d) is used for the simulations
780 shown in the main text of this paper.

781 It is interesting to note that the noise issues and algorithmic remedies found in the
782 real-world simulations discussed above, can be investigated by replacing all of physics
783 with a modified version of the Held-Suarez forcing (Held & Suarez, 1994). The original
784 formulation of the Held-Suarez idealized test case used a flat Earth ($\Phi_s = 0$) and a dry
785 atmosphere. By simply adding the surface topography used in 'real-world' simulations
786 and removing the temperature relaxation in the lower part of domain ($\sigma > 0.7$; see Held
787 and Suarez (1994) for details), surprisingly realistic vertical velocity fields (in terms of
788 structure) result (see Figure A2). Since this was a very useful development tool it is shared
789 in this manuscript.

790 Acknowledgments

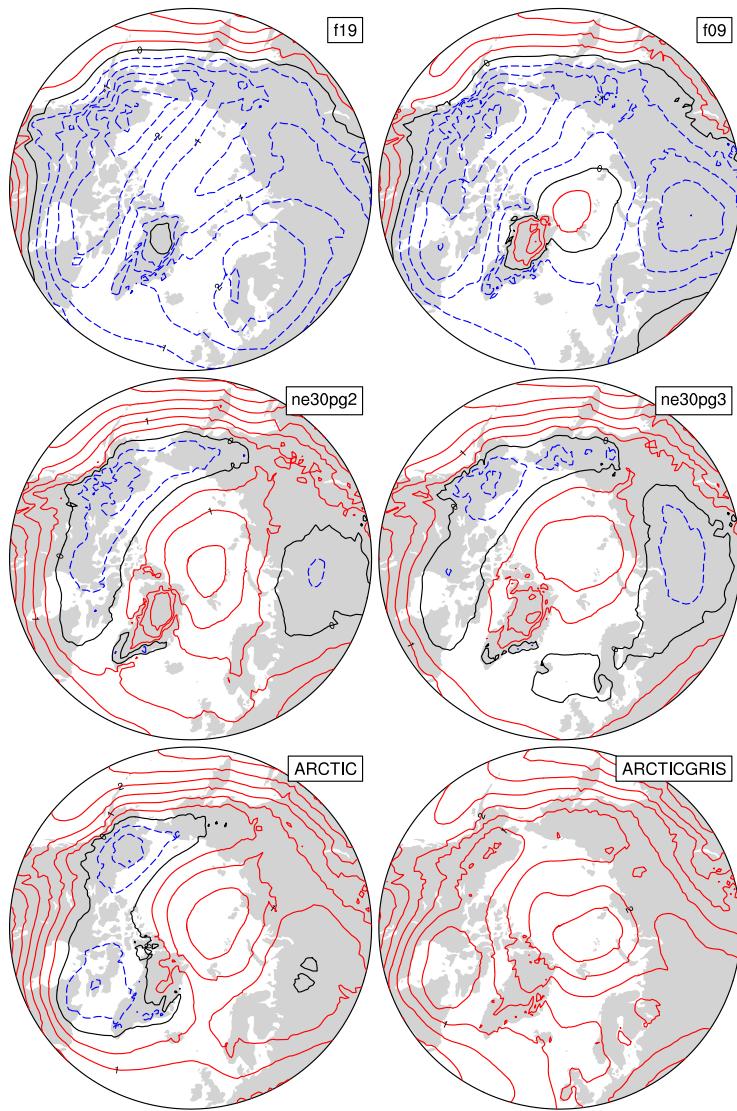

Figure 6. 1979-1998 lower troposphere, northern hemisphere summer virtual temperature biases, computed as the difference from ERA5. Lower troposphere layer mean virtual temperature is derived from the 1000 hPa - 500h Pa geopotential thickness, using the hypsometric equation. Differences are computed after mapping the ERA5 data to the finite-volume grids since the geopotential field is only available on the output tapes in the spectral-element runs that have been interpolated to the f09 grid, inline.

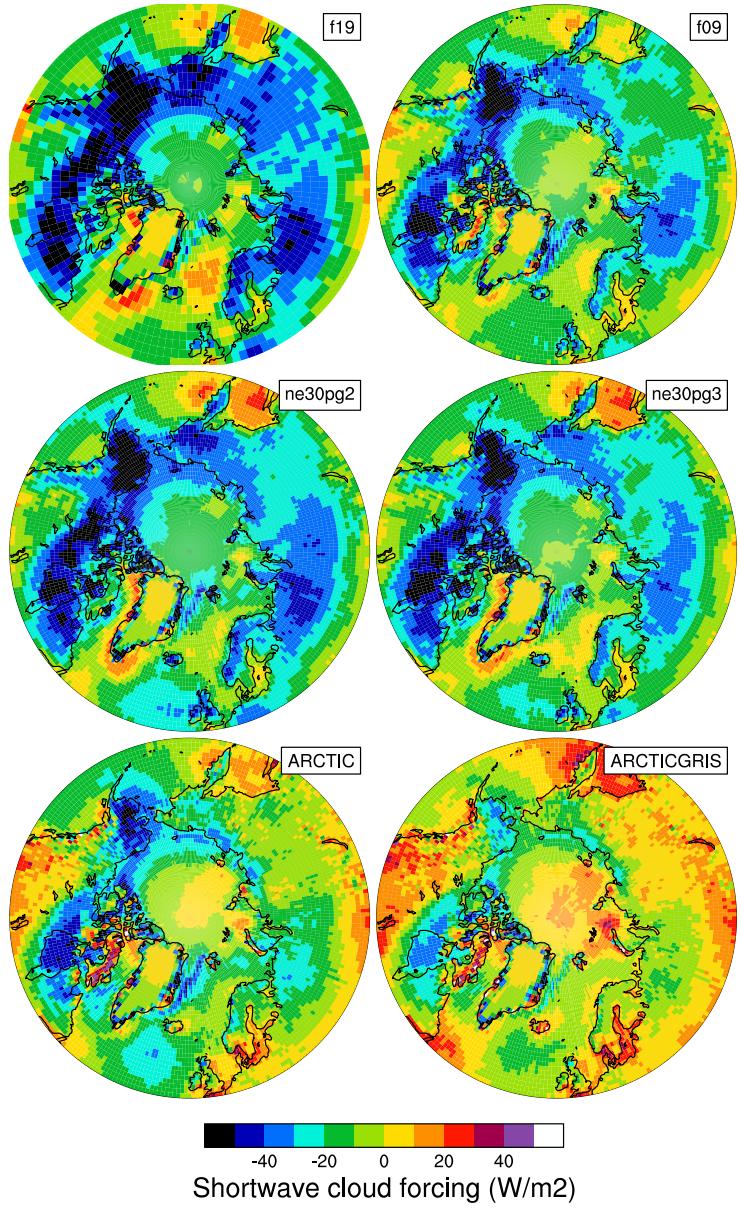

Figure 7. 1979-1998 Northern Hemisphere summer shortwave cloud forcing bias, relative to the CERES-EBAF gridded dataset. Shortwave cloud forcing is defined as the difference between all-sky and clear-sky net shortwave fluxes at the top of the atmosphere. Differences are computed after mapping all model output to the 1° CERES-EBAF grid.

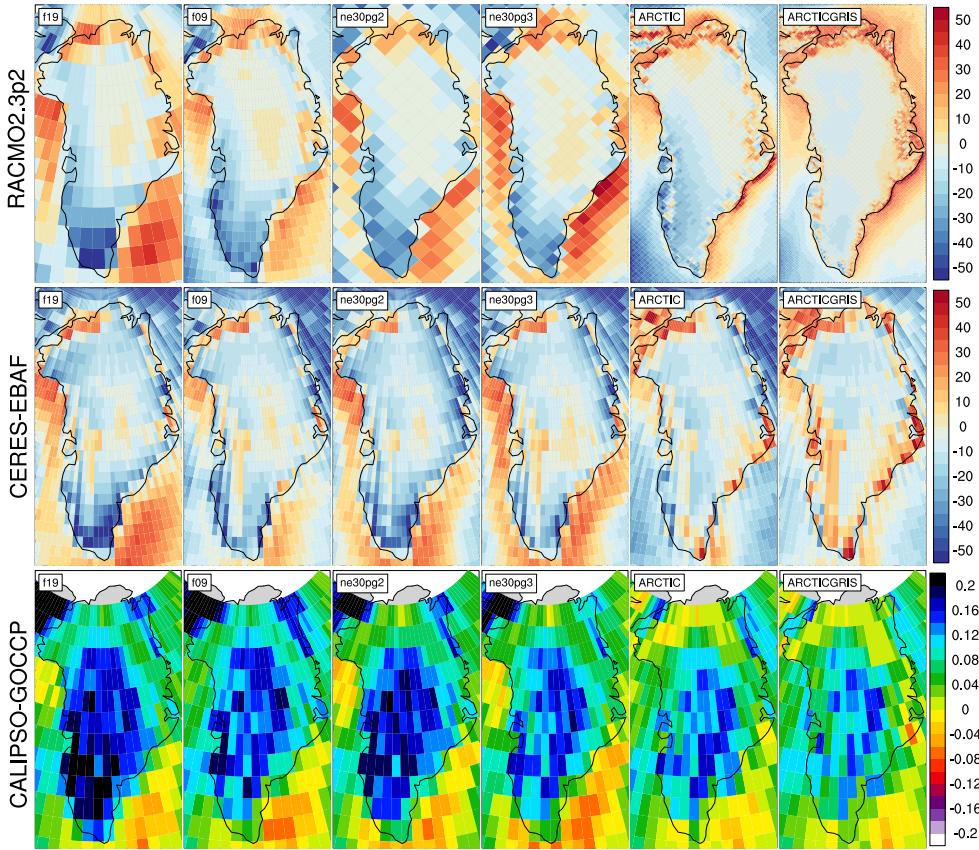

Figure 8. 1979–1998 northern hemisphere summer (top) total cloud fraction bias relative to the CALIPSO dataset and incident shortwave radiation bias (W/m^2), computed as the difference (middle) from CERES, and (bottom) RACMO2.3p2 dataset. The CALIPSO and CERES differences are found by mapping the model output to the 1° grid, and differences in the bottom panel are computed after mapping the RACMO2.3p2 dataset to the individual model grids. Note that the averaging period for the CALIPSO-GOCCP and CERES-EBAF panels, 2006–2017 and 2003–2020, respectively, are different from the averaging period for the model results.

Figure 9. 1979-1998 (top) annual precipitation and (bottom) ice/snow melt biases relative to RACMO2.3p2, evaluated on the native model grids. The precipitation biases are expressed as fractional changes, whereas the melt biases are absolute changes (mm/yr). In the bottom panel, the Rignot and Mouginot (2012) basin boundaries are shown in grey for each model grid. Note that Figure 11 uses the basin boundaries for the two common ice masks, shown in the f19 and ne30pg2 panels, in computing the basin-scale integrals. Blue lines in the f19 panel show the location of the two transects plotted in Figure 12..

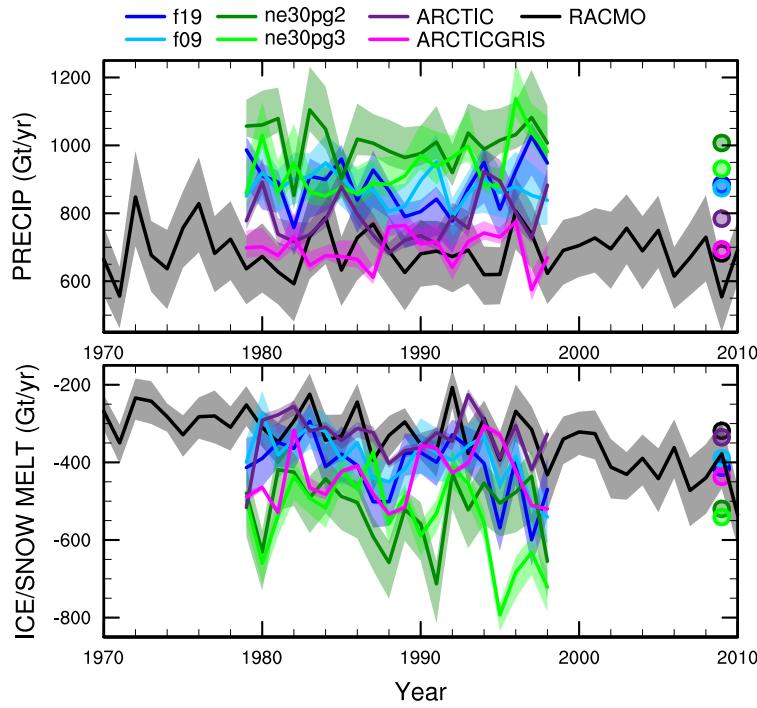

Figure 10. Time-series of annual (solid+liquid) precipitation (top) and annual runoff (bottom) integrated over the Greenland Ice Sheet for all six simulations and compared to the RACMO datasets. The time-series were generated using the common ice mask approach, which results in up to 4 ensembles, with the mean value given by the solid line and shading spanning the extent of the ensemble members.

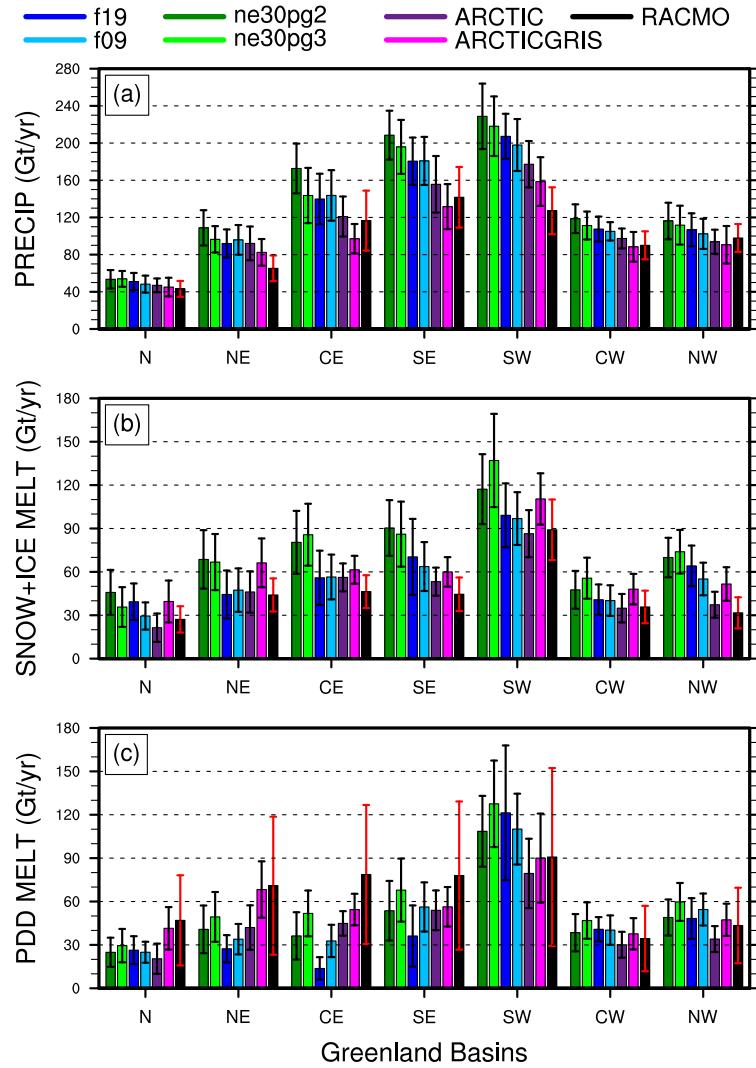

Figure 11. 1979–1998 basin integrated components of the SMB; (top) precipitation, (middle) ice/snow melt and (bottom) ice/snow melt estimated from the PDD method. Whiskers span the max/min of the four ensemble members generated from the common-ice-mask approach. Basin definitions are after Rignot and Mouginot (2012), and are found on the common ice masks using a nearest neighbor approach, and shown in Figure 9.

Figure 12. Model surface elevation along the (top) K-transect, and (bottom) a transect spanning the central dome down to the Kangerlussuaq glacier in southeast Greenland, for all model grids. The reference surface (GMTED) is a 1 km surface elevation dataset used for generating the CAM topographic boundary conditions.

Figure 13. Fractional melt bias over the GrIS, computed relative to the RACMO datasets using the common ice mask approach, and conditionally sampled by grid cell ice fraction provided by the common ice masks. Solid lines are the mean of the distribution with \pm one standard deviation expressed by shading.

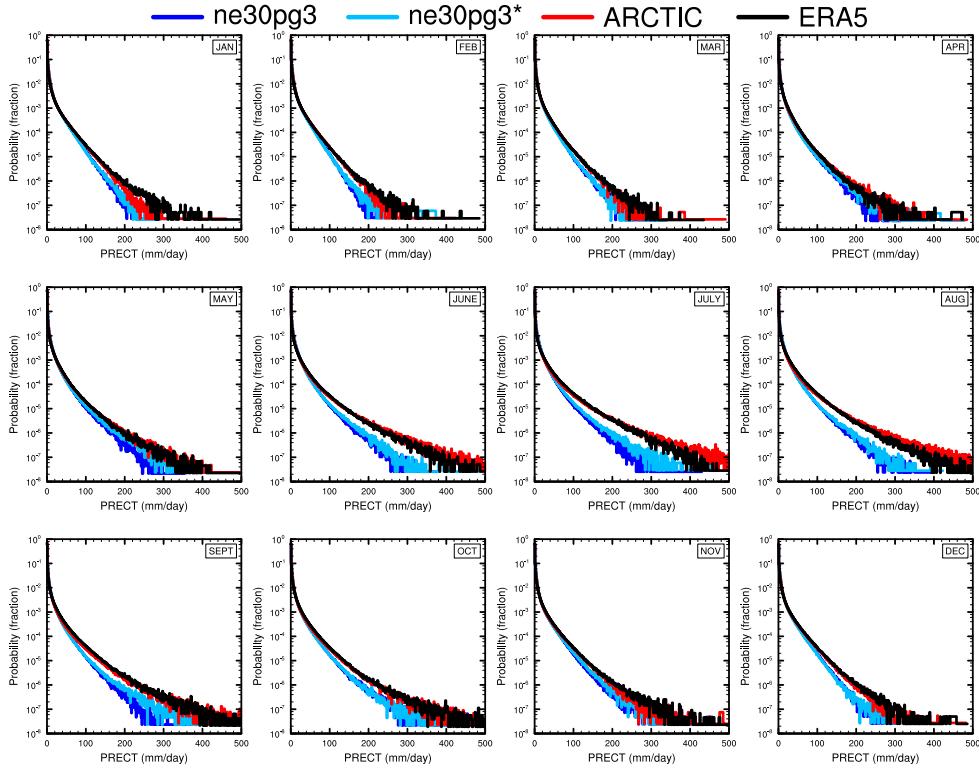

Figure 14. PDFs of the total precipitation rate associated with tracked storms, by month, in the ne30pg3, ne30pg3* and Arctic runs, and compared with the ERA5 dataset.

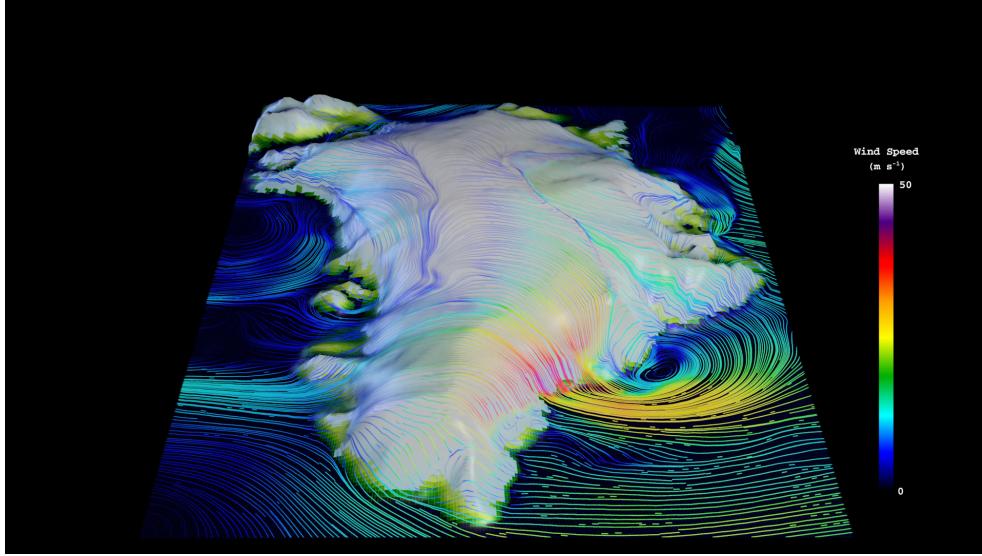

Figure 15. Snapshot of the lowest model level streamlines from the Arctic – GrIS visualization, with color shading denoting the wind magnitude.

OMEGA500, 1 year average, F2000climo, 32 levels

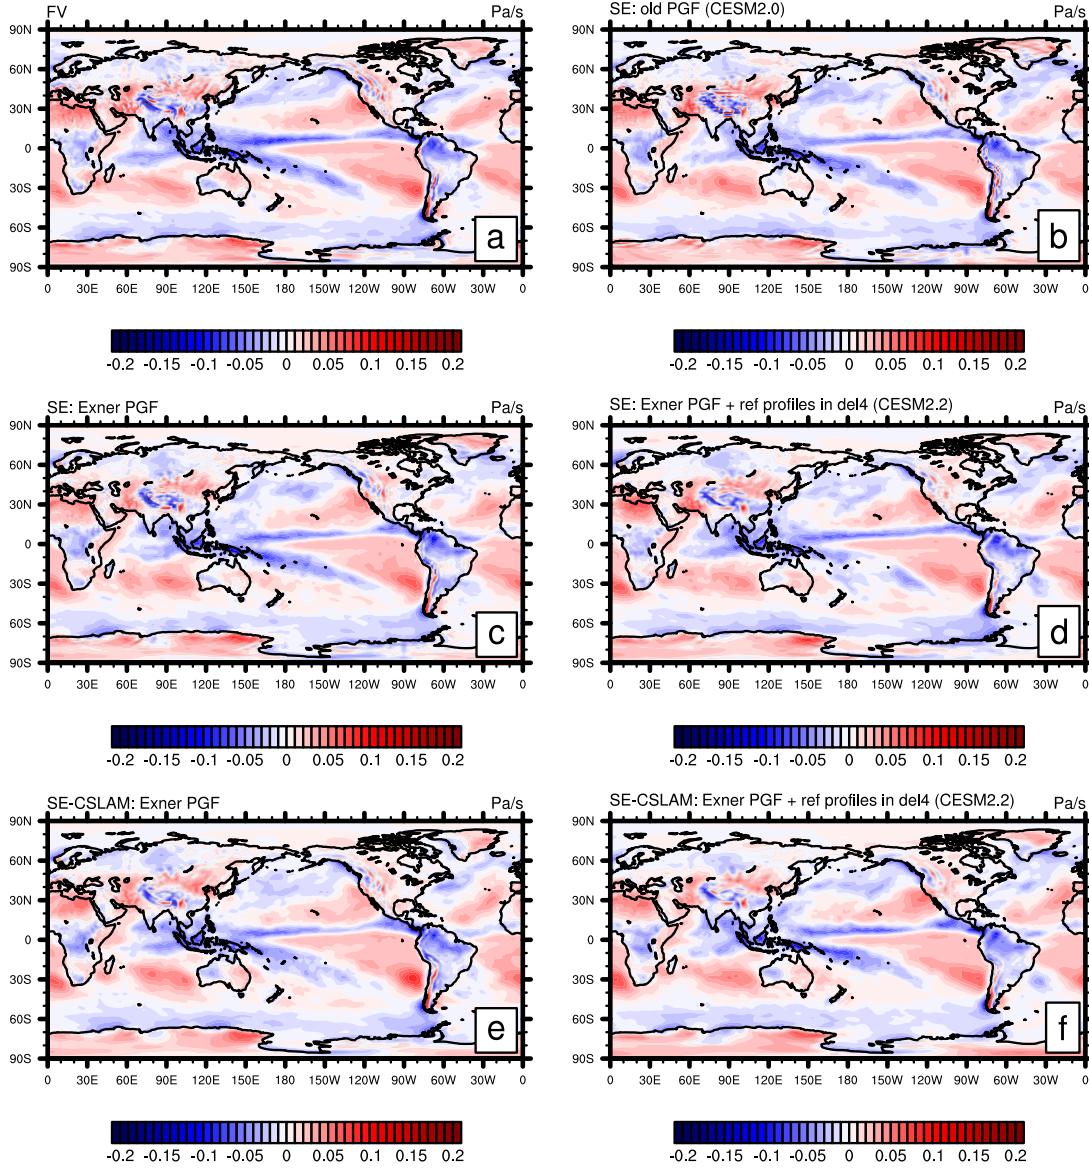

Figure A1. One year averages of vertical pressure velocity at 500hPa (OMEGA500) using (a) CAM-FV (Finite-Volume dynamical core) and (b-f) various versions of the spectral-element (SE) dynamical core at approximately 1° horizontal resolution and using 32 levels. (b) is equivalent to the CESM2.0 version of the SE dynamical core using the "traditional"/"old" discretization of the pressure-gradient force (PGF). Plot (c) is equivalent to configuration (b) but using the Exner form of the PGF. Plot (d) is the same as configuration (c) but also subtracting reference profiles from pressure and temperature before applying hyperviscosity operators (which is equivalent to the CESM2.2 version of SE in terms of the dynamical core). Plots (e) and (f) are equivalent to (c) and (d), respectively, by using the SE-CSLAM (ne30pg3) version of the SE dynamical core (i.e. separate quasi-uniform physics grid and CSLAM transport scheme).

OMEGA500, 18 months average, FHS94 forcing, 32 levels

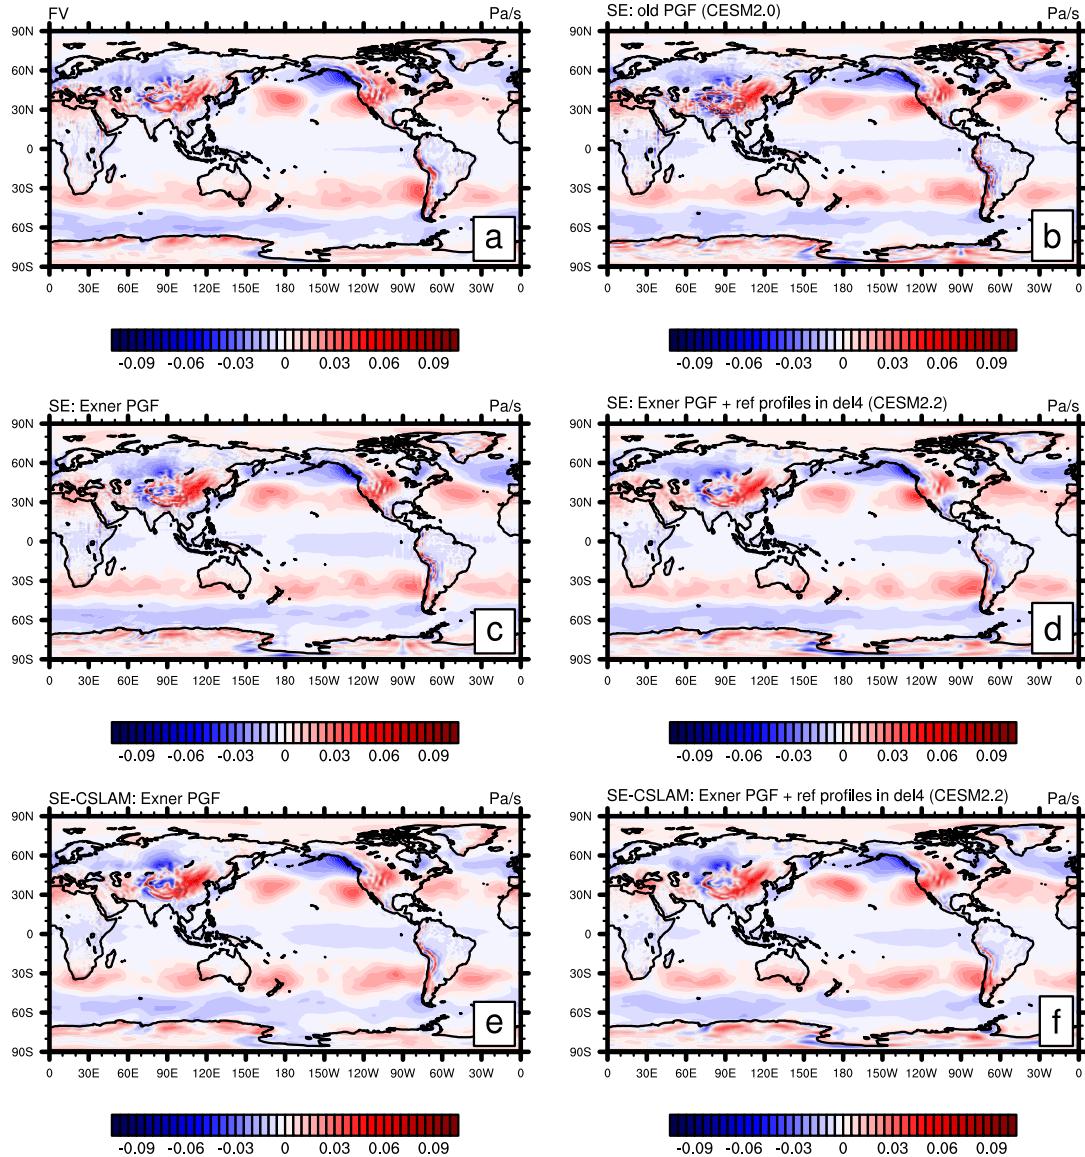

Figure A2. Same as Figure A1 but using modified Held-Suarez forcing and the average is over 18 months (excl. spin-up).
